Abstract

Pulsed-laser deposition has been used to grow epitaxial thin films of the giant-dielectric-constant material CaCu$_3$Ti$_4$O$_{12}$ on LaAlO$_3$ and SrTiO$_3$ substrates with or without various conducting buffer layers. The latter include YBa$_2$Cu$_3$O$_y$, La$_{1.85}$Sr$_{0.15}$CuO$_{4+y}$ and LaNiO$_3$. Above 100K - 150K the thin films have a temperature independent dielectric constant as do single crystals. The value of the dielectric constant is of the order of 1500 over a wide temperature region, potentially making it a good candidate for many applications. The frequency dependence of its dielectric properties below 100K - 150K indicates an activated relaxation process.
Ferroelectric or relaxor materials, such as (Ba, Sr)TiO$_3$ (BST) \cite{1}, SrTiO$_3$ (STO) \cite{2} and KTa$_{1-x}$Nb$_x$O$_3$ (KTN) \cite{3}, have been widely studied for various electronics applications, including dynamic random access memory (DRAM). This is because, in general, a high static dielectric constant is only observed in either a ferroelectric or a relaxor material. However, both types of material show a peak in the dielectric constant as a function of temperature, making it undesirable for many applications because a strong temperature dependence may cause the related device to fail with temperature variations in the environment. Recently CaCu$_3$Ti$_4$O$_{12}$ (CCTO) was discovered to have an extraordinarily high dielectric constant $\sim$ 80,000 at room temperature with minimal temperature dependence above 100K. \cite{4, 5, 6}

No ferroelectric lattice distortion has been observed by either high-resolution X-ray \cite{5} or neutron powder diffraction \cite{4}, posing interesting questions: why does the material have such a giant dielectric constant and why does the latter decrease dramatically below 100K. It is therefore of considerable interest both from a fundamental and an application point of view to see whether one can make thin films of this material and examine its properties. In this letter, we show that high quality CCTO thin films can be epitaxially grown on various substrates with or without conducting buffer layers. The low frequency dielectric constant is lower than that of the single crystal, but still $\sim$ 1500 over a wide temperature region, making it a competitive candidate for many applications.

The CCTO thin films were grown by pulsed laser deposition (PLD) on LaAlO$_3$ (LAO) or STO substrates, as well as YBa$_2$Cu$_3$O$_7$ (YBCO), La$_{1.85}$Sr$_{0.15}$CuO$_{4+\delta}$ (LSCO) and LaNiO$_3$ (LNO) buffer electrode layers. These electrode layers were also deposited on the substrates \textit{in situ} by PLD before the deposition of the CCTO thin film. The CCTO target was prepared by solid state reaction with the purity of the powders confirmed by X-ray powder diffraction. A KrF excimer laser (wavelength: 248 nm) was used with an energy density of $\sim$ 2.0 J/cm$^2$ and a repetition rate of 5 Hz. The substrate was heated to 720°C (800°C for the YBCO layer). An oxygen pressure of 200 mTorr was used during the deposition for all materials. After deposition, the films were cooled to room temperature at a rate of 60°C per minute. Au pads, 0.5 mm$^2$ in area with a thickness of about 4000 Å, were thermally evaporated to form a parallel-plate capacitor structure. Due to the difficulty of etching the CCTO thin films while maintaining the film quality, contacts were made to two of the top Au pads effectively, allowing the capacitance to be measured in two capacitors connected in series by the bottom electrodes. Dielectric constants and loss tangents were measured by a Keithley
Thin films grown directly on STO substrates do not have the correct phase or may have more than one orientation of CCTO. This is understandable since the lattice mismatch between STO and CCTO is large. CCTO has a cubic structure with a lattice constant \(a = 7.36 \text{ Å} \) \((a/2 = 3.68 \text{ Å})\), while STO has a cubic lattice constant \(a = 3.905 \text{ Å}\). Thin films grown on the LAO substrate have only one orientation. This is shown in Fig.1 (a) in a \(\theta - 2\theta\) X-ray diffraction scan. Only the \((l00)\) peaks from CCTO are present indicating that the out-of-plane alignment is good. The substrate temperature and the oxygen pressure were found to be crucial for single phase formation of CCTO. Indeed thin films deposited at 780°C or 20 mTorr were found to include the \((310)\) orientation. In order to make dielectric measurements, various conducting perovskite oxides were fabricated as the bottom electrodes. Shown in Fig.1 (b) is a \(\theta - 2\theta\) scan of a 6000 Å CCTO thin film on a 1500 Å LSCO buffer layer on the STO substrate. Only the \((00l)\) peaks from both CCTO and LSCO layers are present in the spectrum with peaks from the STO substrate, indicating both layers grow with the \(c\)-axis perpendicular to the substrate surface. It is worth pointing out that, with a LSCO buffer layer, the CCTO thin films can also be grown epitaxially on a STO substrate.

The in-plane epitaxy of the CCTO thin films were examined by \(\phi\) scans. Fig.2 shows the results of such a scan from the same bilayer thin film as in Fig.1 (b). Sharp peaks appear with 90° intervals for both the CCTO and LSCO layers, and the STO substrate, indicating the \(a\) axis of the CCTO and LSCO layers are well aligned with the substrate. Combined with the \(\theta - 2\theta\) scan, it shows we have an excellent epitaxy between the CCTO thin film, the LSCO buffer layer and the STO substrate. Thus we are in a position to study the properties of CCTO in thin film format.

Because LNO has a lattice constant closer to CCTO than YBCO and a much better conductivity than LSCO, we made our measurement on thin films of CCTO/LNO/LAO. The temperature dependence of the dielectric constant and loss tangent for such a film at various frequencies from 200Hz to 100kHz is shown in Fig.3 (a) and (b) respectively. The dielectric constant has a fairly high value at room temperature, but, unlike the single crystal data, with a large frequency dependence. It decreases rapidly with decreasing temperature. The loss tangent shows the same trend with temperature. In fact both are very similar to the very first report by Subramanian et al. at high temperature. Below a temperature of 250K, the film behaves almost exactly the same as a single crystal. The dielectric constants
at all frequencies have a constant value of the order of 1500 until about 100K - 150K, when they decrease rapidly to approximately 200. This value is different from that of the single crystal, which is about 100. Obviously, the system undergoes a transition from a high $\varepsilon$ state at high temperature to a low $\varepsilon$ state at low temperature and the frequency dependence only takes place around the transition temperature regime, which is about 100K - 150K. The transition takes place at higher temperatures at higher frequencies. Correspondingly, the peak observed in the temperature dependence of the loss tangent, shifts toward higher temperature. Finally, it is interesting to note that the results shown in Fig.3 are very similar to those from the bulk material CdCu$_3$Ti$_4$O$_{12}$, which does not have the same giant dielectric constant at room temperature as bulk CCTO.

The large dielectric constant of CCTO has been interpreted as an extrinsic mechanism, which was assumed to come from the sample microstructure such as boundary or interface effects. In fact, one recent paper has claimed that CCTO is a one-step internal barrier layer capacitor. With such a model, one would conclude that the thin films have less defects than the single crystals because of their lower dielectric constant. This is a possibility though it can often be the reverse. Thin films, with their much reduced size in one dimension, may have less planar defects, such as grain boundaries and twin interfaces, than single crystals, particularly if the latter have a large amount of intrinsic planar defects. Comparing the data from the single crystals and the thin films, it seems that the constant value of dielectric constant in a certain temperature region and the decrease at low temperature is a consistent property of the material, presenting an interesting problem as to why the dramatic increase at even higher temperature only shows up in thin films or polycrystalline samples.

The dielectric constant also has a significant dependence on the thickness of the CCTO thin films. To date, thin films with a thickness less than 3000 Å have a much lower dielectric constant ($\sim$700). However it should be possible to improve this by further optimizing the growth conditions, such as oxygen pressure and cooling rate after the deposition or different conducting bottom electrode layer. These studies as well as thickness dependence of the dielectric properties will be published elsewhere.

Finally, it is worth pointing out that the loss tangent in the thin film is actually lower than in the single crystal. This may well be a reflection that the single crystals have more defects than the thin films. Since the low temperature decrease of the dielectric constant towards 100 or 200 is certainly associated with the peak observed in the temperature dependence of
the loss tangent, this might just be due to the fact that the constant value (∼1500) of the dielectric constant in the thin film is much lower than in the single crystal (>10,000). A precise description should involve an understanding of the observed peak. Homes et al. used a Debye relaxation model to describe the frequency dependence of the dielectric constant and find a thermally activated behavior with an activation energy of about 630K in single crystal. Here we show a simple way to get a similar result from our loss tangent data. In Fig.4, we plotted the frequency on a logarithmic scale versus the inverse peak temperature in our loss measurement. Along with the thin film data we also show the data from a single crystal. Clearly a linear dependence is observed, indicating that \( f \sim \exp(-U_0/kT) \), in both sets of data. \( U_0 \) for the single crystal is 690K which is about the same as the value from fitting to the Debye relaxation model for the dielectric constant. \( U_0 \) for the thin film is 880K. The difference may well reflect the fact that the thin film is under strain due to the lattice mismatch. Of course, the microstructure and defects and domain difference would also play a role. Further study on the evolution of the activated relaxation with thin film thickness will be conducted.

In conclusion, we have successfully grown epitaxial CCTO thin films by pulsed laser deposition. Thin films have similar properties to the previously studied single crystals. The dielectric constant is above 1500 within a fairly large temperature region, making it a very attractive material for many applications. Further investigations including the thickness dependence and electric field dependence are under way.
